Theme 4	Portable electronic diagnostic and fault detection systems.
Theme 5	Fail-safe timing and power management protection systems.

Theme 1: Analog sensing for industrial applications.

1. In many industrial panels and lab benches, technicians must quickly judge whether DC control lines (5–24 V) are too low, normal, or dangerously high without using a multimeter each time. Design a compact multi-range DC line status indicator that converts the input voltage into three clear LED states (LOW/OK/HIGH) using only resistor dividers and 2–3 basic comparator or transistor threshold stages, suitable for permanent mounting on panels.
2. Field engineers often carry several AA and 9 V batteries but have no easy way to know which ones are still usable under load. Develop a pocketsized battery health tester that can test AA and 9 V cells under realistic load current, use a scaling divider and two threshold stages, and show exactly one LED (GOOD/WEAK/DEAD) per battery so that a technician can instantly decide whether to keep or discard it.
3. In power electronics labs, students and technicians need a simple visual way to monitor the temperature of heat sinks or small setups to avoid overheating without using expensive digital thermometers. Create an analog temperature bar indicator that converts the voltage from an NTC thermistor into a 3–5 LED bargraph using a resistor ladder and multiple

comparator/transistor stages, with clearly separated LED thresholds representing safe, warm, and hot regions.

4. Many workspaces (e.g., soldering benches, small enclosures, or plant growth setups) need a quick visual indication of whether lighting is sufficient or too dim without a calibrated lux meter. Build a light-intensity tester that uses an LDR and resistor ladder to map ambient light into 3–5 discrete LED levels via multiple threshold stages, so that users can immediately judge if lighting is poor, acceptable, or bright enough for their application.
5. In electronics labs, students frequently work with low-voltage AC test transformers and signals but cannot tell at a glance whether AC is present or at an adequate amplitude. Implement a low-voltage AC presence and amplitude tester that rectifies and filters the AC signal, then uses a simple threshold stage to drive LEDs indicating “AC OK” and optionally “AC LOW”, enabling quick go/no-go checks on test points without connecting an oscilloscope.
6. In shared robotics labs, students often power small robots from bench supplies but cannot see if the 12 V rail has sagged into a “danger zone” that can reset controllers but still spin motors. Design a plug-on 12 V rail sentinel that clips across the supply and, using dividers plus 2–3 comparator/transistor stages, drives three LEDs to indicate “under-voltage risk”, “OK for logic + motors”, and “over-voltage threat”, suitable for permanent mounting on a robot test stand.
7. School robotics clubs accumulate mixed AA and AAA cells from competitions but lack a quick way to decide which ones are still strong enough for motor drivers versus only safe for remote controls. Develop a benchtop battery sorter that, using only a push button, selectable load resistor, and simple threshold/LED logic, classifies each inserted AA or AAA cell into “robot-ready”, “only for remotes/sensors”, or “discard” based on its loaded voltage behaviour over a short test window
8. In low-cost 3D printer enclosures, operators need a quick visual sense of how hot the stepper-driver area is getting without installing full digital thermostats. Create a small thermal bargraph module using an NTC thermistor, resistor ladder, and comparator stages that mounts

near the driver heatsink and shows four ranges on LEDs: “cool”, “warm”, “hot – check cooling”, and “critical – stop print”.

9. DIY photography lightboxes for product shots often rely only on the photographer’s eye to judge if the LED panels are bright enough for consistent images. Build a compact “photo light adequacy badge” using an LDR, resistor ladder, and threshold stages that mounts inside the box and uses 3–5 LEDs to show “too dim”, “usable for web”, “good for print”, and “risk of overexposure” so users can reproduce lighting conditions.

10. In small SMPS design labs, students test isolation transformers but cannot easily see whether the secondary amplitude is within the safe window for their rectifier and regulator prototypes. Implement a bench AC readiness indicator that rectifies and filters the secondary voltage, then uses simple thresholds to drive LEDs for “no AC”, “AC below design range”, and “AC in/above design range” for typical 9–18 V AC windings.

Theme 2: Digital logic systems for automation and safety control.

1. In lab experiments and small test jigs, instructors often need to count how many times a button was pressed or a sensor was triggered without using microcontrollers. Design a 0–9 event counter using a counter IC (such as CD4029/7490/CD4017) with a debounced push-button input and LED indication, ensuring each count from 0 to 9 has a unique binary or decoded LED pattern and can be reliably reset to zero during demonstrations.
2. During basic digital electronics experiments, students frequently need a simple way to monitor up to four events (like switch closures or small sensor outputs) but typically rely on complex setups. Develop a singlechannel 0–3 pulse counter using two flip-flops or a small counter IC where each clean input pulse advances a 2-bit LED display through 00,

01, 10, and 11, with robust debouncing and a manual reset so it can act as a straightforward event logger on the bench.

3. In small control rigs such as miniature conveyor or pump demonstrators, operators require a clear RUN/STOP status that remains latched even after buttons are released. Create a RUN/STOP status memory latch using NAND/NOR gates (or cross-coupled BJTs) that takes input from two pushbuttons and drives dedicated RUN and STOP LEDs, reliably remembering the last command so that the machine's state is always unambiguous to the operator.
4. Industrial systems sometimes generate very brief fault pulses that are easy to miss visually but must be latched and examined later. Implement a fault memory latch using an RS latch and suitable input conditioning that captures even short FAULT events, turns an alarm LED ON, and keeps it ON until a user presses a reset button, making it useful as a simple fault logger on control panels.
5. Maintenance engineers may need to know not just whether a fault occurred, but how many times it has happened up to a small count before a reset. Build a 0–3 fault counter using a 2-bit counter (flip-flops or an IC) that increments each time a fault pulse arrives, shows the count in binary on two LEDs, and includes a clear manual reset function, enabling quick diagnosis of intermittent issues without any microcontroller.
6. In bottle-filling training rigs, trainees must track how many bottles passed a sensor in each batch without using displays or microcontrollers. Design a rugged 0–9 bottle counter using a counter IC and LED pattern display that increments on eachsensor pulse, provides a "batch done" output at 9, and can be manually reset between runs..
7. In shuttle-run fitness tests, coaches need a simple handheld device to count a few laps per athlete without losing track while watching form. Develop a palm-sized 0–3 lap tracker using a debounced push button and 2-bit LED display that can be quickly reset between athletes and is robust enough for outdoor use.
8. For model railway control boards, hobbyists need a clear indication of whether the layout logic is currently commanding trains to run or

remain halted, even after many button presses. Create a front-panel RUN/STOP latch using basic logic gates and two large LEDs so that the last command is clearly visible from across the room and survives brief power drops.

9. On motor-starter training panels, brief overload trips may occur too quickly for students to notice on ordinary indicator lamps. Implement a fault capture module that latches any short "overload" pulse into a red LED that stays on until manually reset, making each event visible for discussion during lab sessions.
10. During EMC stress tests on a prototype board, engineers want to know if glitch-induced faults are rare or frequently repeating over a test interval. Build a 2-bit fault counter that sits between a glitch detector and the rest of the circuit, increments a 2-bit LED display for each detected fault up to 3, and shows "3+" when faults occur repeatedly.

Theme 3: Audio-based human interaction and safety sensing systems.

1. In audio labs and repair shops, technicians often need to quickly check whether a microphone or small audio source is alive without setting up an amplifier and speaker system. Design a single-transistor audio tester in common-emitter configuration that takes input from a mic or audio line and drives a small speaker or buzzer, providing a clear audible difference between silence, weak signals, and normal speech or tones.
2. Stage technicians and students regularly plug in electret microphones but cannot easily confirm if the mic capsule and wiring are intact before an event. Develop a "tap-to-test" microphone checker using an electret mic, transistor amplifier, rectifier, and hold capacitor that flashes an LED reliably on taps or loud speech while ignoring normal background noise, allowing a one-button go/no-go check before a performance or recording.
3. Many households and service centers have multiple IR remote controls but no quick way to verify if a remote is actually transmitting when a

button is pressed. Create an IR remote-control tester that uses a photodiode or phototransistor front-end and an NPN amplifier to drive an LED, so that whenever a remote is pointed at the tester and a button is pressed, the LED blinks in visible bursts, confirming remote functionality at typical usage distances.

4. In small audio setups such as classroom PA systems or DIY speakers, users often struggle to judge if the input level is too low, optimal, or clipping. Implement a 3-LED audio-level meter that rectifies and smooths an audio signal, then compares it with low, medium, and high reference levels using LM324/LM339 or transistor thresholds, so each LED lights only when its corresponding level is exceeded and the overall loudness can be seen at a glance.
5. Workshops, labs, and makerspaces need a simple way to indicate when ambient noise exceeds a safe or comfortable level without installing complex sound-level meters. Build a noise-level warning indicator using an electret mic, amplification, rectification, and a threshold transistor stage that turns an LED ON only when the noise crosses an adjustable "too loud" threshold, helping supervisors maintain a safer acoustic environment.
6. At school events, volunteers often connect phones or laptops to a PA system without knowing whether the audio cable or jack is faulty. Design a pocket-sized audio cable tester that takes input from a 3.5 mm jack, amplifies it using a single-transistor CE stage, and drives a small speaker so users can quickly confirm that both channels and ground are intact.
7. Podcasting clubs and AV labs commonly face issues where a mic "seems dead" during recording, only to discover loose wiring later. Develop a desktop mic diagnostic tool where plugging in a mic and tapping or speaking triggers a deliberately slow-decay LED flash (via rectifier plus hold capacitor), making intermittent connection issues obvious compared to a stable mic.
8. In home-theatre installation jobs, technicians need to verify that universal IR extenders correctly transmit remote commands from a hidden location to the receiver. Create a compact IR relay tester that uses a photodiode front-end and amplifier to drive a visible LED

which blinks in proportion to IR bursts arriving at the extender's output, confirming that commands are passing through the system.

9. In karaoke bars using simple analog mixers, staff struggle to set mic levels so that guests are audible over the music without constant distortion. Implement a small 3-LED mic-level widget using rectification and comparator thresholds that mounts near the mic input and indicates "too soft", "good singing level", and "clipping likely" as the gain is adjusted.
10. In shared hostel study rooms, noise gradually increases during group sessions until it disturbs others, but students have no objective feedback. Build a wall-mounted noise sentinel using an electret mic, amplifier, and threshold stage to drive a large LED or tower light when average sound level exceeds a set limit, encouraging occupants to lower conversation or move to common areas.

Theme 4: Portable electronic diagnostic and fault detection systems.

1. Electricians and lab users frequently check wiring or PCB tracks for continuity but may not want to keep switching a multimeter to continuity mode. Design a handheld continuity tester with buzzer that uses a transistor stage to detect low-resistance connections between two probes and produces a clear beep only for near-short conditions, staying silent for high resistance or open circuits to avoid confusion.
2. In electronics labs, many salvaged or unknown NPN transistors are reused, but their health (open, short, or low gain) is uncertain. Develop a transistor good/bad tester with clearly labelled B-C-E pads, mode selection, and 2–3 LEDs that can distinguish normal gain behavior from shorts or opens, allowing users to quickly validate components using only LED patterns without any measurement instruments.
3. Hobbyists and students often cannot identify the polarity or health of loose diodes and LEDs pulled from scrap boards. Create a diode/LED

polarity and health tester that applies a small current in both directions using a DPDT switch or dual push-buttons, and uses indicator LEDs to show correct forward conduction, reverse blocking, or abnormal bothways/no-conduction behavior so that devices can be sorted quickly into usable and faulty bins.

4. Touchless switches and automatic dispensers rely on detecting the presence of a hand or object using simple sensors. Implement an LDRbased hand proximity tester that forms a light-dependent divider feeding

   a transistor, such that covering the sensor with a hand reliably crosses a threshold and turns an LED ON, demonstrating the core principle of lightbased presence detection for low-cost interactive devices.

5. When reusing old electrolytic capacitors from scrap boards, their leakage and ability to hold charge are often unknown but critical for reliability. Build a capacitor leakage / charge-hold tester that charges a capacitor to a fixed voltage, then isolates it and lets it discharge only through an LED and resistor; the LED fade time should give a clear visual comparison between healthy low-leakage capacitors and leaky or degraded ones.

6. In solar-panel installation labs, students must trace long DC strings and verify that each string is truly continuous and not partially broken under connectors. Design a handheld continuity probe with LED and buzzer that gives a clear response only for very low resistance, helping distinguish fully healthy strings from those with high series resistance.

7. In analog design courses, students often salvage transistors from old boards for experiments but need a quick way to check both health and rough gain category. Develop a bench transistor sorter with labelled B-C-E pads and LED patterns that indicate “faulty”, “low gain”, “medium gain”, or “high gain” for general-purpose NPN devices

8. Makerspaces receive assorted loose diodes, LEDs, and unknown two-terminal parts from donations, making it hard to decide how to reuse them. Create a universal two-terminal evaluator where a single control reverses polarity and indicator LEDs reveal conduction

direction and approximate forward voltage, helping classify parts as “silicon diode”, “Schottky-like”, “LED-type”, or “faulty/short”.

9. Touchless lamp prototypes for hostel rooms need a simple analog front-end that senses a hand wave near the lampshade before designers add complex control logic. Implement a proof-of-concept hand proximity detector using an LDR and transistor so that moving a hand near the sensor toggles an LED output clearly between OFF and ON states.
10. Component-reuse drives in colleges often involve sorting large numbers of electrolytic capacitors pulled from scrap, but checking them one-by-one is too slow. Build a multi-slot capacitor leakage station where each capacitor is charged to the same voltage and then allowed to discharge only through its own LED and resistor, letting users compare leakage by observing fade times side-by-side

Theme 5: Fail-safe timing and power management protection systems.

1. Many small DC loads like fans and lamps draw a high inrush current if turned on immediately at power-up, potentially stressing lab supplies or demo setups. Design an ON-delay start module using an NE555 monostable, RC timing network, and transistor/relay or MOSFET that waits for a preset time before energizing the load, so that loads can be sequenced smoothly in lab experiments or small control panels.
2. Equipment such as soldering stations or power amplifiers often need their cooling fans or pumps to continue running for a short time after the main power is switched off to prevent heat build-up. Develop an OFFdelay stop module using an NE555 monostable that is triggered when the main control signal goes low and keeps the fan or pump ON for an adjustable interval, providing repeatable cooling behaviour without any microcontroller.

3. Simple DC motor speed control or LED strip dimming in hobby projects is often done by varying voltage, which is inefficient and unstable. Create an adjustable duty-cycle PWM controller using an NE555 in astable

   mode, with a potentiometer and diodes to separately control charge and discharge times of the timing capacitor, driving a transistor/MOSFET so that users can smoothly adjust motor speed or light brightness at constant supply voltage.

4. In sensor systems with very narrow pulses (e.g., from encoders or limit switches), LEDs or slow circuits cannot reliably show or process such short events. Implement a pulse-stretching circuit using a 555 or transistor monostable that takes very short input pulses and outputs longer, fixed-width pulses that can be easily observed on an LED or interfaced to slower logic, making invisible events visible for debugging.

5. Embedded controllers and PLCs often provide a “heartbeat” signal to show they are running, but basic indicator LEDs cannot reveal when this periodic signal silently stops. Build a heartbeat watchdog circuit for a logic line using RC charge/decay and a transistor or 555, such that an LED remains ON while pulses keep arriving and automatically turns OFF after a designed timeout when pulses stop, giving a clear visual indication of system hang or failure.

6. In project exhibitions, several demonstration modules must turn on in a specific sequence (e.g., logo lights first, then motors) to look professional and avoid all loads starting together. Design an ON-delay module with NE555 and relay/MOSFET that can be cascaded so different loads power up with adjustable staggered delays from a single main switch.

7. In small compressor-based water coolers with no controller, a fan should keep running for a short period after the compressor stops to prevent hot spots, but only simple electronics are allowed. Develop an OFF-delay driver using a 555 monostable and power transistor that detects when compressor power goes low and keeps the fan running for an adjustable cooldown time

8. Educational conveyor models in labs need low-cost DC speed control so students can study how duty cycle affects torque and motion without software. Create an NE555-based PWM speed controller with

a duty-cycle knob and diode-shaped timing network that drives a transistor or MOSFET to control a DC motor at constant supply voltage.

9. Limit switches on fast training conveyors generate very narrow pulses that are almost invisible on simple LEDs, confusing beginners. Implement a pulse extender module using a transistor or 555 monostable so that each short input pulse produces a clearly visible, fixed-length LED flash and an extended logic pulse for slower circuits

10. On PLC and microcontroller demo racks, instructors want a small independent unit that clearly shows if the controller's periodic "alive" signal has stopped, indicating a hang. Build a heartbeat monitor using an RC network and a transistor or 555 so an LED shows "healthy periodic activity" while pulses arrive and turns off or changes pattern after a set timeout when pulses stop
